

# Parallel & Distributed Computing

## NETWORKS OF WORKSTATIONS (DISTRIBUTED MEMORY)

**Dr. Muzamil Ahmed** (Assistant Professor)  
Namal University Mianwali

# Lesson from Quran

2

وَالَّذِينَ جَاهَدُوا فِينَا لَنَهْدِيَنَّهُمْ سُبُلَنَا<sup>ج</sup>

And those who strive for Us – We  
will surely guide them to Our ways.

Surah al-Ankabut (29:69)

# Lecture Outline

3

- Workstation
- Network of Workstations (NOW)
- Architecture & Communication Mechanism in NOW
- Berkeley NOW Project (Case Study)
- NOW vs Multiprocessors
- Distributed Memory
- Data Distribution and Partitioning
- Issues in Distributed Memory
- Shared vs Distributed Memory

# Workstation

4

- ❑ Workstation, a high-performance computer system as compared to mainstream personal computers, that is basically designed for a single user and has ***advanced graphics capabilities, large storage capacity,*** and a ***powerful central processing unit.***
- ❑ A workstation is ***more capable than a personal computer*** (PC) but is ***less advanced than a server*** (which can manage a large network of peripheral PCs or workstations and handle immense data-processing and reporting tasks).

# Definition - Networks of Workstations

5

- A **Network of Workstations (NOW)** is:
  - ▣ A collection of interconnected, autonomous computers (workstations) that work together to perform parallel or distributed computing tasks over a high-speed local area network (LAN).
- **Key Aspects:**
  - ▣ Each node is a **fully functional workstation** (CPU, memory, OS).
  - ▣ All nodes are connected via **fast communication links**.
  - ▣ Nodes collaborate as if they were part of a **single, unified computing system**.

<https://www.sciencedirect.com/topics/computer-science/workstation-network>

# Networks of Workstations

6

- High-speed networks and rapidly improving microprocessor performance make ***networks of workstations*** an increasingly ***appealing system for parallel computing***.
- By relying solely on commodity hardware and software, networks of workstations offer parallel processing at a relatively low cost.
- ***Commodity hardware*** (unlike ***purpose-built hardware***), sometimes known as ***off-the-shelf hardware***, is a computer device or IT component that is relatively ***inexpensive, widely available*** and basically ***interchangeable with other hardware*** of its type.

# Architecture Overview

7

- ❑ **Workstations (Nodes)**
  - ▣ Independent computers with full OS
  - ▣ Perform local and distributed computation
- ❑ **Network Interconnect**
  - ▣ High-speed LAN (Ethernet, Myrinet, InfiniBand)
  - ▣ Provides data transfer and communication
- ❑ **Middleware/Software Layer**
  - ▣ Handles communication, synchronization, and resource management
  - ▣ Examples: MPI, PVM, RPC frameworks
- ❑ **Resource Manager / Scheduler**
  - ▣ Allocates jobs and balances load dynamically

# Communication Mechanisms

8

## □ Message Passing Paradigm:

- ▣ Processes communicate via **explicit messages**.
- ▣ Communication handled using **network protocols (TCP/IP)**.
- ▣ Libraries and tools:
  - MPI (Message Passing Interface)
  - PVM (Parallel Virtual Machine)
  - RPC (Remote Procedure Calls)

## □ Performance Factors:

- ▣ **Latency:** Time to start message transmission.
- ▣ **Bandwidth:** Amount of data transmitted per second.
- ▣ **Overheads:** Protocol stack, buffering, and synchronization delays.

Message Passing Model

# Implementation Differences between MPI, PVM, and RPC (1)

9

| Aspect                  | MPI (Message Passing Interface)                                                                                                                                                                      | PVM (Parallel Virtual Machine)                                                                                                         | RPC (Remote Procedure Call)                                                                                                                                                   |
|-------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Basic Nature            | A <b>standardized library specification</b> (not a single implementation). Implemented as optimized libraries (e.g., MPICH, OpenMPI).                                                                | A <b>software framework/daemon-based system</b> that creates a “virtual machine” across heterogeneous nodes.                           | A <b>communication protocol abstraction</b> that enables procedure calls across networked systems.                                                                            |
| Process Management      | MPI <b>does not manage processes</b> — the processes are typically started together (e.g., via mpirun or mpiexec). It assumes all processes are already running and are part of the MPI environment. | PVM <b>manages processes dynamically</b> through its <b>pvmd daemon</b> . It can spawn, add, or remove hosts and processes at runtime. | RPC has a <b>client–server model</b> . The server provides callable procedures, and clients invoke them on demand. Process management is external (handled by OS or runtime). |
| Communication Mechanism | Direct <b>point-to-point</b> or <b>collective communication</b> between processes using low-level protocols (TCP/IP, Infiniband, shared memory).                                                     | Communication handled by <b>PVM daemon</b> which intermediates message routing between tasks.                                          | Underlying communication uses <b>request–reply</b> model. Message passing is hidden — stub code (marshalling/unmarshalling) handles serialization.                            |
| Architecture Type       | <b>Peer-to-peer</b> — all processes are equal participants in computation.                                                                                                                           | <b>Master-slave</b> or <b>virtual machine</b> model with centralized control through pvmd daemon.                                      | <b>Client–server</b> — one side provides services, the other requests them.                                                                                                   |
| Performance             | Very <b>high performance</b> — uses optimized communication libraries (zero-copy, RDMA).                                                                                                             | <b>Lower performance</b> due to daemon overhead (indirect communication path).                                                         | <b>High latency</b> compared to MPI/PVM, as it’s designed for infrequent service calls, not high-frequency parallel communication.                                            |

# Implementation Differences between MPI, PVM, and RPC (2)

10

|                                  |                                                                                                                        |                                                                                               |                                                                                                                            |
|----------------------------------|------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------|
| <b>Scalability</b>               | Scales efficiently to <b>thousands of processes</b> (supercomputers, clusters).                                        | Scales well to moderate-size heterogeneous systems (hundreds of nodes).                       | Limited scalability — meant for <b>distributed systems</b> , not parallel HPC workloads.                                   |
| <b>Programming Model</b>         | Explicit <b>message passing</b> via API calls like MPI_Send, MPI_Recv, MPI_Bcast, etc.                                 | Similar API (e.g., pvm_send, pvm_recv), but with extra features for dynamic host management.  | Implicit communication — looks like a normal function call (remote_add(x,y)), implemented via <b>stubs and skeletons</b> . |
| <b>Fault Tolerance</b>           | Limited built-in fault recovery; failures usually abort the job (though some implementations support fault tolerance). | Supports <b>dynamic fault recovery</b> — failed hosts can be replaced or restarted.           | Built-in fault reporting (return codes, exceptions) but <b>no automatic recovery</b> .                                     |
| <b>Implementation Complexity</b> | Implemented as an <b>optimized library layer</b> tightly integrated with the OS/network stack.                         | Implemented as a <b>middleware layer</b> with background daemons managing tasks and messages. | Implemented as <b>middleware + compiler-generated stubs</b> , handling data serialization/deserialization.                 |
| <b>Use Case in PDC</b>           | High-performance parallel computing (HPC), clusters, supercomputers.                                                   | Networks of heterogeneous workstations (NOW), grid-style distributed computing.               | Distributed applications, microservices, and networked systems (not HPC).                                                  |

# Berkeley NOW Project (Case Study)

11

- **University of California, Berkeley (1990s)**
- **Goal:** To build a high-performance computing platform using **commodity workstations and a fast network**.
- **Key Innovations:**
  - ▣ High-speed **Myrinet** network interconnect
  - ▣ **NOW-FS (Global File System)** for shared access
  - ▣ **Efficient process migration** and load balancing
  - ▣ Developed **Active Messages** — a low-latency communication mechanism
- **Impact:**
  - ▣ Demonstrated feasibility of using workstation networks for parallel workloads
  - ▣ Inspired Beowulf clusters and early grid computing

# NOW vs Multiprocessors

12

| Feature         | Multiprocessor                  | Network of Workstations    |
|-----------------|---------------------------------|----------------------------|
| Architecture    | Shared memory                   | Distributed memory         |
| Communication   | Through shared bus              | Through network links      |
| Scalability     | Limited (due to bus contention) | High (add more nodes)      |
| Fault Tolerance | Single point of failure         | Independent nodes          |
| Cost            | High                            | Low                        |
| Example         | Intel Xeon SMP                  | Berkeley NOW, LAN clusters |

# Concept of Distributed Memory

13

- ❑ In a **distributed memory system**, each processor (workstation) has its **own private memory**.
- ❑ No global address space — memory cannot be directly accessed by other nodes.
- ❑ All data sharing occurs through **explicit message passing**.
- ❑ Each node executes part of a program and communicates results when necessary.
- ❑ **Example:** A NOW of 10 Linux PCs connected by Gigabit Ethernet forms a distributed memory system.

# Data Distribution and Partitioning

14

## □ Challenges:

- ▣ How to divide large data across multiple nodes efficiently.
- ▣ How to minimize communication overhead.

## □ Strategies:

- ▣ **Block Distribution** – Divide array into equal-sized blocks assigned to nodes.
- ▣ **Cyclic Distribution** – Elements distributed round-robin style to balance load.
- ▣ **Block-Cyclic Distribution** – Combines benefits of both for irregular workloads.

# Block Distribution

15

- The dataset (e.g., an array or matrix) is **divided into contiguous blocks**, and each block is assigned to a specific node (processor or workstation).
- Each processor owns a **complete block** of data (responsible for computing results on its portion independently).
- Suppose we have an array of 16 elements:  $A = [1, 2, 3, \dots, 16]$ , With 4 processors (P0–P3) and **block size = 4**, distribution becomes:
- $P0 \rightarrow [1, 2, 3, 4]$ ,  $P1 \rightarrow [5, 6, 7, 8]$ ,  $P2 \rightarrow [9, 10, 11, 12]$ ,  $P3 \rightarrow [13, 14, 15, 16]$
- **Limitations**
  - ▣ Load imbalance may occur when different parts of data take unequal processing time.
  - ▣ Not ideal for irregular workloads or when all processors need parts of all data.

# Cyclic Distribution for Load Balancing

16

- Elements are distributed among processors in a **round-robin (cyclic) fashion**.
- Each node receives **every nth element**, ensuring that work is evenly spread even if tasks take varying amounts of time.
- Using the same array  $A = [1, 2, 3, \dots, 16]$  with 4 processors:
- $P0 \rightarrow [1, 5, 9, 13]$ ,  $P1 \rightarrow [2, 6, 10, 14]$ ,  $P2 \rightarrow [3, 7, 11, 15]$ ,  $P3 \rightarrow [4, 8, 12, 16]$ 
  - ▣ Element  $i$  is assigned to processor  $i \bmod p$ .
- **Limitations:**
  - ▣ **Increased communication** — since processors need non-local data more often.
  - ▣ **Cache locality** decreases — as elements handled by each node are dispersed in memory.

# Block-Cyclic Distribution – Balancing Load and Locality

17

- A hybrid of **Block** and **Cyclic** distribution strategies.
- Data is divided into **small blocks**, and these blocks are then distributed cyclically among processors.
- Balances **load distribution** (like cyclic) while maintaining **data locality** (like block).
- Consider 16 elements, 4 processors, and block size = 2:
- $P0 \rightarrow [1,2], [9,10]$ ,  $P1 \rightarrow [3,4], [11,12]$ ,  $P2 \rightarrow [5,6], [13,14]$ ,  $P3 \rightarrow [7,8], [15,16]$ 
  - ▣ Blocks of 2 elements are cyclically assigned to processors.
- Advantages:
  - ▣ Load-balanced like cyclic distribution.
  - ▣ Preserves spatial locality by grouping elements in small blocks.
  - ▣ Highly flexible for both regular and irregular computations.

# Process Communication

18

- Each node executes a process that communicates via **message passing**.
- Communication mechanisms:
  - ▣ **Point-to-point:** send/receive between two processes.
  - ▣ **Collective:** broadcast, gather, scatter, reduce operations.
- Implemented using libraries such as:
  - ▣ **MPI\_Send(), MPI\_Recv()** (MPI)
  - ▣ **pvm\_send(), pvm\_recv()** (PVM)

# Performance Issues in Distributed Memory

19

- ❑ **Network latency:** time to initiate communication.
- ❑ **Bandwidth:** rate of data transfer.
- ❑ **Granularity:** size of tasks—fine-grained tasks → more communication.
- ❑ **Synchronization overhead:** waiting for other nodes.

# Programming Issues in Distributed Memory

20

- The key issue in *programming* distributed memory systems is *how to distribute the data over the memories*.
- Depending on the problem solved, the data can be *distributed statically*, or it can be *moved through the nodes*.
- Data can be *moved on demand*, or data can be *pushed to the new nodes in advance*.

# Programming Issues in Distributed Memory

21

- Data can be *kept statically* in nodes if *most computations happen locally*, and only changes on edges have to be reported to other nodes.
- An example of this is simulation where *data is modeled* using a *grid* (non-interactive workloads), and *each node simulates a small part of the larger grid*.
- On every iteration, nodes **inform** all neighboring nodes of the new edge data.

# Shared vs. Distributed Memory

22

- There are two kinds of multiple-processor systems exist:
  - ▣ **Multi-Processors** (Shared/ Distributed)
  - ▣ **Multi-Computers** (Distributed)
- In a **multi-processor** two or more CPUs **share a common main memory**.
- Any ***process*** on any ***processor***, can read or write any word in shared memory, simply by moving data to or from the desired location.
- In a **multi-computer**, in contrast, **each CPU has its own private memory**. Nothing is shared.

# Shared vs. Distributed Memory

23

- ❑ To make an **agriculture analogy**, a multiprocessor is a system with a **herd of sheep (*processes*)** eating from a **single feeding through (*shared memory*)**.
- ❑ A **multicomputer**, on the other hand, is a design in which each sheep has its own **private feeding through (*distributed memory*)**.

# Summary & Discussion

24

- Distributed memory = each node has **private memory** and communicates via **messages**.
- NOW systems are **distributed-memory architectures** implemented using networked workstations.
- Achieve parallelism through **data partitioning, message passing, and synchronization**.
- Trade-off between **performance** and **programming complexity**.

# Thanks
